Hierarchical Clustering and Consensus in Trust Networks

Santiago Segarra  Alejandro Ribeiro

University of Pennsylvania

Abstract—We apply recent developments in clustering theory of asymmetric networks to study the equilibrium configurations of consensus dynamics in trust networks. We show that reciprocal clustering characterizes the equilibrium opinions of mutual trust dynamics. That is, clusters in the reciprocal dendrogram correspond to different equilibrium opinions of mutual trust consensus for varying trust thresholds. Moreover, for unidirectional trust dynamics, we show that aggregating nonreciprocal clusters into single nodes does not modify reachability of global consensus, thus, simplifying the consensus analysis of large networks.

I. INTRODUCTION

Consensus or agreement problems in networked systems have been extensively studied in the last decade with a wide range of applications [1]. Formation control [2] and flocking [3] among other problems have been approached through a consensus perspective. Furthermore, consensus dynamics have been used to model opinion propagation in social networks [4], [5]. In this context, agents update their own opinion by considering the opinion of their neighbors, i.e., a subset of the community which they trust.

In society, trust relations arise between individuals and can be modeled through a trust network. We all have an idea of how much we trust other members of our society like relatives, friends, or acquaintances. However, it is unclear if we should trust more the friend of a relative or a direct acquaintance. More generally, it is unclear who should we trust within a network or, equivalently, who belongs to our circle of trust. We use hierarchical clustering [6, Ch. 4] to model these concerns. In particular, we apply recent developments [7], [8] to hierarchically cluster asymmetric networks.

When sharing opinions in society, it is reasonable to filter whose opinions to take into account depending on the issue being discussed. E.g., for a simple and public issue, we might trust the opinion of a large set of agents in our community whereas when it comes to intimate and private matters we only rely on close friends. In this context, for every trust threshold we have different consensus dynamics and, thus, different equilibrium configurations. Our main contribution is the relation between the hierarchical clustering of a trust network and the consensus equilibria for different trust thresholds of this network. In particular, reciprocal clustering determines the equilibria when mutual trust is required for propagation and nonreciprocal clustering informs about the equilibria when unidirectional trust is enough for propagation.

II. PRELIMINARIES

Define a network \(N = (X, A_X)\) as a set of \(n\) nodes \(X\) endowed with a real valued dissimilarity function \(A_X : X \times X \rightarrow \mathbb{R}_+\) defined for all pairs of nodes \(x, x' \in X\). Dissimilarities \(A_X(x, x')\) are nonnegative for all \(x, x' \in X\), and null if and only if \(x = x'\), but need not satisfy the triangle inequality and may be asymmetric, i.e., \(A_X(x, x') \neq A_X(x', x)\) for some \(x, x' \in X\). When we hierarchically cluster a network \(N = (X, A_X)\), we obtain a dendrogram \(D_X\), i.e., a nested set of partitions \(D_X(\delta)\) indexed by the resolution parameter \(\delta \geq 0\); see e.g. Fig. 6 and Fig. 7-(a). Partitions in a dendrogram \(D_X\) must satisfy two boundary conditions: for the resolution parameter \(\delta = 0\) each node \(x \in X\) forms a singleton cluster, i.e., \(D_X(0) = \{(x), x \in X\}\), and for some sufficiently large resolution \(\delta_0\) all nodes must belong to the same cluster, i.e., \(D_X(\delta_0) = \{X\}\). Partitions being nested implies that if any two nodes \(x, x' \in X\) are in the same cluster at a given resolution \(\delta'\) then they stay co-clustered for all larger resolutions \(\delta > \delta'\). If two nodes \(x, x' \in X\) belong to the same cluster at resolution \(\delta\) in dendrogram \(D_X\) then we write \(x \sim_{D_X(\delta)} x'\). For a given dendrogram \(D_X\), we denote by \(u_X(x, x')\) the minimum resolution at which nodes \(x, x'\) are co-clustered, i.e.,

\[
u_X(x, x') := \min \{\delta \geq 0, x \sim_{D_X(\delta)} x'\}.
\]  

A hierarchical clustering method is then a map \(H : N \rightarrow \mathcal{D}\) mapping every network in \(N\) to a dendrogram in \(\mathcal{D}\). Two clustering methods of interest are reciprocal and nonreciprocal clustering [7]. The reciprocal clustering method \(H^R\) with output dendrogram \(D_X^R\) merges nodes \(x, x'\) at resolution \(u_X^R(x, x')\) given by

\[
u_X^R(x, x') := \min_{C(x, x')} \max_{i \in C(x, x')} A_X(x_i, x_{i+1}),
\]  

where \(A_X(x, x') := \max(A_X(x, x'), A_X(x', x))\) for all \(x, x' \in X\). Intuitively, in (2) we search for chains \(C(x, x')\) linking nodes \(x, x'\). Then, for a given chain, walk from \(x\) to \(x'\) and determine the maximum dissimilarity, in either the forward or backward direction, across all links in the chain. Then \(u_X^R(x, x')\) is the minimum of this value across all possible chains; see Fig. 1.

Reciprocal clustering joins \(x\) to \(x'\) by going back and forth at maximum cost \(\delta\) through the same chain. Nonreciprocal clustering \(H^{NR}\) permits different chains. Define the minimum directed cost as

\[
u_X^{NR}(x, x') := \min_{C(x, x')} \max_{i \in C(x, x')} A_X(x_i, x_{i+1}),
\]  

and the nonreciprocal merging resolution as the maximum of the two minimum directed costs from \(x\) to \(x'\) and \(x'\) to \(x\)

\[
u_X^{NR}(x, x') := \max \left(\nu_X^{NR}(x, x'), \nu_X^{NR}(x', x)\right).
\]  

In (4) we implicitly consider forward chains \(C(x, x')\) going from \(x\) to \(x'\) and backward chains \(C'(x', x)\) from \(x'\) to \(x\). We then determine the respective maximum dissimilarities and search independently for the

Thanks to AFOSR MURI FA9550-10-1-0567 and NSF CCF-1217963.
forward and backward chains that minimize the respective maximum dissimilarities. The nonreciprocal merging resolution \( u_N^{(x)}(x, x') \) is the maximum of these two minimum values; see Fig. 2.

In the present paper we also consider directed, unweighted graphs \( G = (X, E) \) on the node set \( X \), where \( E \subseteq X \times X \) is the edge set. By definition, \( E \) does not contain self-loops. For every node \( x \), we define its neighborhood \( E_x \) as the subset of nodes where the edges starting at \( x \) end, i.e. \( E_x := \{ x' \in X \mid (x, x') \in E \} \). We also define the adjacency matrix \( A_G = [a_{ij}] \) of graph \( G \) as a binary matrix where

\[
a_{ij} = 1 \quad \text{if } (x_i, x_j) \in E \quad \text{and} \quad a_{ij} = 0 \quad \text{otherwise}.
\]

The degree matrix \( D_G \) is a diagonal matrix with \( D_{ii} = |E_{x_i}| \) and \( D_{ij} = 0 \) for \( i \neq j \). The Laplacian matrix \( L_G \) associated with graph \( G \) is then given by

\[
L_G = \Delta_G - A_G. \tag{5}
\]

In this paper we focus on the continuous time consensus dynamics given by

\[
\dot{p}(t) = -L_G \ p(t), \quad p(0) = p_0, \tag{6}
\]

where \( p(t) \in \mathbb{R}^n \) for all times \( t \), with \( p_i(t) \) describing the state – or opinion in our context – of node \( x_i \) at time \( t \). In the dynamics given by (6), the change in a given node’s opinion is determined by the average disagreement with its neighbors. I.e., if my opinion is equal to the average of my neighbors’ opinion, then my opinion will remain unchanged for the next time instant. We say that global consensus is reached when every node converges to the same opinion.

### III. TRUST NETWORKS AND CONSENSUS DYNAMICS

Define a trust network \( N = (X, A_X) \) as one where nodes \( x \in X \) represent agents, e.g. people in society, and \( A_X(x, x') \) represents a measure of how much \( x \) distrusts \( x' \), i.e. \( A_X(x, x') < A_X(x', x) \) implies that \( x \) trusts more in \( x' \) than in \( x'' \). Notice that the function \( A_X \) is inherently asymmetric since trust relations between people need not be bidirectional. Indeed, it is usually the case in social networks that some influential agents, say celebrities or politicians, are heard by a big portion of the network but they do not take into account the opinions of all of their followers.

If we want to model opinion propagation through consensus in a trust network, one possibility is extending (5) and (6) for weighted graphs as considered in, e.g., [9]. In this case, an agent weighs the importance of others’ opinions depending on how much he trusts them. However, we consider different dynamics where the neighborhood of an agent is a function of the issue being discussed in the network. E.g., if we need advice on where to have dinner we trust the opinion of a larger set of people than when we need advice on how to approach a relationship problem. Thus, a given trust network \( N \) has associated an infinite number of consensus problems indexed by a trust threshold parameter \( \delta \). In this way, for low values of \( \delta \) we only listen to the opinion of our intimate circle of trust whereas for large values of \( \delta \) we admit the opinion of more distant acquaintances. In this paper, we consider two different ways of determining neighborhoods given a trust parameter \( \delta \): mutual and unidirectional trust.

#### A. Mutual trust consensus

Given a trust network \( N = (X, A_X) \), in mutual trust consensus we require that for two agents \( x \) and \( x' \) to share their opinions they should distrust each other less than a given threshold \( \delta \). In other words, communication between agents only occurs when there is a minimum of trust in both directions. Hence, given a trust network \( N \) and a threshold \( \delta \) we define the mutual communication graph \( G_N(\delta) = (X, E) \) with adjacency matrix \( A_{G_N}(\delta) \) given by

\[
[A_{G_N}(\delta)]_{ij} = \begin{cases} 
1 & \text{if } A_X(x_i, x_j) \leq \delta \quad \text{and} \quad A_X(x_j, x_i) \leq \delta, \\
0 & \text{otherwise},
\end{cases}
\]

for all \( i \neq j \) and \( [A_{G_N}(\delta)]_{ii} = 0 \) for all \( i \). To facilitate understanding refer to Fig. 3. Note that definition (7) is symmetric implying that the graph \( G_N(\delta) \) is undirected for all \( \delta \geq 0 \).

From (5), we compute the Laplacian matrix \( L_{G_N}(\delta) \) for every resolution \( \delta \) and obtain the mutual trust consensus dynamics

\[
\dot{p}(t) = -L_{G_N}(\delta) \ p(t), \quad p(0) = p_0, \tag{8}
\]

which is just a specialization of (6) for a particular Laplacian matrix. Note that in (8) we actually have an infinite number of consensus problems indexed by the resolution parameter \( \delta \). We are interested in the equilibrium configuration \( \lim_{t \to \infty} p(t) \) of the consensus, i.e. the opinions of the agents after a long time has elapsed. When \( \delta = 0 \), we obtain \( A_{G_N}(0) = L_{G_N}(0) = 0 \) implying that there is no communication at all. In this situation, every node in the network preserves its original opinion through time. On the other hand, for a sufficiently large resolution \( \delta = \delta_0 \), the adjacency network is that of a complete graph and global consensus is achieved. For resolutions in between, we want to characterize local equilibrium configurations.

#### B. Unidirectional trust consensus

In unidirectional trust consensus, for a given agent to be influenced by the opinion of another, the first agent must trust the second one independently of the trust relation in the inverse direction. Given a trust network \( N = (X, A_X) \) and a trust threshold \( \delta \) we
the reciprocal clustering method converges to the same opinion through consensus dynamics. Indeed, circular matter then you would trust that same person with a more trivial circle of trust. Moreover, it is reasonable for the circles of trust to determine the extent of our circle of trust, i.e. an intimate matter nodes form our circle of trust? This question is in fact ill-posed

\[
\frac{dX}{dt} = -L\delta G_N^e(x_i, x_j) p(t), \quad p(0) = p_0, \tag{10}
\]

which contains an infinite number of consensus problems indexed by the resolution parameter \(\delta\). The extremal results for \(\delta = 0\) and \(\delta = \delta_0\) sufficiently large guaranteeing \(G_N^e(\delta_0)\) to be a complete graph, coincide with the mutual trust case in (8). As for mutual trust, we are interested in characterizing the equilibrium for intermediate resolutions.

IV. CIRCLES OF TRUST AND CONSENSUS EQUILIBRIA

We are all part of trust networks in our social lives, thus motivating the question: who should we trust? or equivalently, which nodes form our circle of trust? This question is in fact ill-posed as discussed in Section III since the issue being discussed would determine the extent of our circle of trust, i.e. an intimate matter determines a close circle whereas a trivial matter admits an extended circle of trust. Moreover, it is reasonable for the circles of trust to be nested in the sense that if you trust someone with a very intimate matter then you would trust that person with a more trivial issue. Hence, dendrograms are natural representations for circles of trust in networks, where the resolution parameter \(\delta\) denotes the level of intimacy of the issue in discussion, with lower \(\delta\) denoting more intimate matters. Consequently, we can reinterpret hierarchical clustering methods \(H\) as maps that assign a nested collection of circles of trust \(H(N)\) to every trust network \(N\).

It is reasonable to expect agents in the same circle of trust to converge to the same opinion through consensus dynamics. Indeed, the reciprocal clustering method \(H^R\) solves the mutual trust problem (8) as the following proposition asserts.

**Proposition 1** In the mutual trust consensus dynamics (8) with parameter \(\delta\), for every initial condition \(p_0\),

\[
\lim_{t \to \infty} p_i(t) = \lim_{t \to \infty} p_j(t) \iff u^R_N(x_i, x_j) \leq \delta, \tag{11}
\]

where \(u^R_N\) is defined as in (2).

**Proof:** See [10].

Proposition 1 implies that the reciprocal dendrogram of a given trust network contains information about opinion convergence for the infinite family of consensus problems in (8) indexed by \(\delta\). To explain this assertion, consider the five-node trust network \(N\) in Fig. 4.

For the case of the unidirectional trust consensus problem in (10), an equivalence result as the one found in Proposition 1 is impossible since the clusters of nodes converging to the same opinion are not nested. To see this, consider the graphs \(G_N^e(1)\) and \(G_N^e(1.5)\) induced by network \(N\) in Fig. 4. For \(G_N^e(1)\), we have that \(x_3\) listens to \(x_1\) and will eventually converge to his opinion while \(x_2\) preserves his original opinion through time. Thus, there are two opinions in equilibrium.
network in Fig. 5 for resolution directional trust consensus dynamics. Proposition 2 value corresponding to the least dissimilar pair. Global consensus member of the equivalence class $A$. The dissimilarity to the same cluster at resolution space nodes network. In order to explain this precisely, we need to define the data while maintaining the global consensus behavior of the original (10). Indeed, nonreciprocal clustering is the correct way to aggregate provide insight to further understand the consensus dynamics in a dendrogram.

For the larger resolution $\delta = 1.5$, we have that in $G_\delta^N(1.5)$, $x_3$ listens to both $x_1$ and $x_2$ and will reach their average opinion in equilibrium while $x_1$ and $x_2$ maintain their original opinions. This outputs three different equilibrium opinions. Thus, opinion clusters are not nested as we modify the resolution parameter and cannot be represented by a dendrogram.

Nonetheless, nonreciprocal clustering $H^{NR}$ as defined in (4) does provide insight to further understand the consensus dynamics in (10). Indeed, nonreciprocal clustering is the correct way to aggregate data while maintaining the global consensus behavior of the original network. In order to explain this precisely, we need to define the network of equivalence classes $N_\delta^2$ at a given resolution $\delta$. Recall that nodes $x$ and $x'$ belong to the same nonreciprocal cluster at resolution $\delta$, i.e., $x \sim_{D_\delta^N} x'$, if and only if $u^N_{XR}(x, x') \leq \delta$. Consider the space $Z^\delta := X \mod \sim_{D_\delta^N}$ of equivalence classes and the map $\phi_\delta : X \rightarrow Z^\delta$ that maps each point of $X$ to its equivalence class. Notice that $x$ and $x'$ are mapped to the same point $z$ if they belong to the same cluster at resolution $\delta$, that is

$$\phi_\delta(x) = \phi_\delta(x') \iff u^N_{XR}(x, x') \leq \delta.$$ (12)

We define the network $N_\delta^2 = (Z^\delta, A_\delta^Z)$ by endowing $Z^\delta$ with the dissimilarity function $A_\delta^Z$ derived from the dissimilarity $A_X$ as

$$A_\delta^Z(z, z') = \min_{x \in \phi_\delta^{-1}(z), x' \in \phi_\delta^{-1}(z')} A_X(x, x').$$ (13)

The dissimilarity $A_\delta^Z(z, z')$ compares all the dissimilarities $A_X(x, x')$ between a member of the equivalence class $z$ and a member of the equivalence class $z'$ and sets $A_\delta^Z(z, z')$ to the value corresponding to the least dissimilar pair. Global consensus reachability of networks $N$ and $N_\delta^2$ is equivalent for every resolution $\delta$ as the following proposition asserts.

**Proposition 2** Given a trust network $N = (X, A_X)$, for the unidirectional trust consensus dynamics (10) with parameter $\delta$, the graph $G_\delta^N(\delta)$ reaches global consensus if and only if $G_\delta^{NR}(\delta)$ reaches global consensus where the network of equivalence classes $N_\delta^2 = (Z^\delta, A_\delta^Z)$ is defined in (12) and (13).

**Proof:** See [10].

In general, clustering in networks seeks to aggregate data while preserving relevant features of the original network. Proposition 2 shows that nonreciprocal clustering aggregates the data in $N$ into the equivalence class network $N_\delta^2$ while preserving reachability of global consensus in (10) for every resolution $\delta$. To exemplify this, in Fig. 7-(a) we depict the nonreciprocal dendrogram of the network in Fig. 5 computed with the algorithm in [8]. At resolution $\delta = 2.5$, there are two equivalence classes given by $Z^{2.5} = \{\{x_2, x_3, x_4, x_5\}, \{x_1\}\}$. From (13) we compute $A_\delta^{Z_2}(2.5)$ and we depict the network $N_\delta^2$ at the leftmost part of Fig. 7-(b). From this network we compute the corresponding directed graph $G_\delta^{NR}(2.5)$ using (9) and illustrate it in the rightmost part of Fig. 7-(b). This two-node graph trivially reaches global consensus. Hence, by Proposition 2 we can assert that the five-node graph $G_\delta^N(2.5)$ derived from the network in Fig. 5 also reaches global consensus. Furthermore, in Fig. 7-(b) we see that the node containing $x_2$ through $x_5$ adopts the opinion of $x_1$. Thus, the global consensus opinion of the five-node graph $G_\delta^N(2.5)$ coincides with the original opinion of agent $x_1$.

**V. CONCLUSION**

We applied a theory for hierarchical clustering of asymmetric networks to study equilibrium configurations of consensus problems. Reciprocal clustering was shown to describe opinion profiles in mutual trust consensus problems whereas nonreciprocal clustering was shown to be the right way to aggregate data while maintaining global consensus reachability in unidirectional trust consensus problems.
